

Experiment 3

AIM: Create a Cryptocurrency using Python and perform mining in the Blockchain created.

THEORY:

1. Blockchain Introduction

Blockchain is a decentralized and distributed ledger technology used for securely storing transaction records across multiple computers called nodes. Unlike traditional systems that depend on a central authority, every node in a blockchain network maintains an identical copy of the ledger.

Each block in the blockchain consists of:

- A collection of transactions
- The time at which the block was created
- The hash of the preceding block
- A unique cryptographic hash of the current block

Blocks are connected through cryptographic hashes, forming a continuous chain. If any block data is altered, its hash changes, causing a mismatch with subsequent blocks. This makes unauthorized modification easily detectable and ensures transparency, security, and immutability of data.

2. Mining Process

Mining is the mechanism through which new blocks are created and appended to the blockchain.

It includes:

- Collecting pending transactions
- Creating a block header
- Solving a computationally difficult problem known as Proof-of-Work (PoW)

In the Proof-of-Work method, miners repeatedly modify a nonce value to produce a hash that satisfies a predefined difficulty condition, such as a specific number of leading zeros.

Once a valid hash is discovered, the block is broadcast to the network and added to the blockchain.

Miners are rewarded with cryptocurrency for their computational contribution.

3. Multi-Node Blockchain Setup

In this experiment, a decentralized blockchain environment is implemented using three independent nodes running on different ports (5001, 5002, and 5003).

Each node:

- Functions independently
- Stores its own copy of the blockchain
- Exchanges information with peer nodes

This configuration demonstrates how blockchain networks operate without a centralized server while maintaining data synchronization across nodes.

4. Consensus Mechanism

To maintain uniformity across the network, a consensus strategy known as the Longest Valid Chain Rule is applied.

If multiple blockchain versions exist, the node adopts the longest chain that is verified to be valid. This approach allows the network to resolve temporary inconsistencies and ensures that all

nodes eventually agree on a single, consistent transaction history.

5. Transactions and Mining Incentives

A transaction in a blockchain-based currency system contains:

- Sender's address
- Recipient's address

- Amount to be transferred

When a new block is mined, all pending transactions are recorded within it. In addition, a reward transaction is generated to credit the miner with newly created cryptocurrency. This incentive encourages participants to actively support and secure the blockchain network

CONCLUSION:

In this experiment, we implemented a simple blockchain network across two devices connected within the same network. Each device ran its own blockchain node on port 5000 with endpoints to add transactions, mine blocks, and replace the chain. Using cURL requests, we tested the functionality by successfully adding transactions, mining them into blocks, and attempting to synchronize both devices using the replace chain mechanism. This allowed us to understand how blockchain ensures decentralization, immutability, and consensus across multiple nodes. Although simplified compared to real-world systems, the experiment demonstrated the core principles of blockchain, including how nodes communicate and maintain a consistent ledger, thereby fulfilling the objective of exploring blockchain in a distributed environment.
